Version-controlled CloudFormation deployments using commit ID tagging

Neeti Mishra, Amazon Web Services

May 2026 ([document history](#))

Many organizations that use AWS CloudFormation to define and provision cloud resources face challenges with version tracking and environment consistency. Without a structured versioning strategy, teams struggle to trace which infrastructure code is deployed to which environment, making rollbacks difficult and compliance audits time-consuming. This guide describes an approach that combines Git commit ID-based tagging with version-to-environment mapping by using AWS CodePipeline and AWS CodeBuild. This approach helps teams improve deployment traceability, maintain environment consistency, and control infrastructure changes across development, staging, and production environments.

Intended audience

This guide is intended for DevOps engineers, cloud infrastructure engineers, and platform teams who manage CloudFormation deployments across multiple environments. Readers should have experience with:

- CloudFormation template authoring
- Git version control
- Continuous integration and continuous delivery (CI/CD) pipeline concepts
- AWS Identity and Access Management (IAM) role configuration
- Python scripting

Objectives

After reading this guide, you will be able to:

- Implement semantic versioning for CloudFormation templates by using Git tags
- Configure version-to-environment mapping for controlled deployments

- Set up automated deployment pipelines by using AWS CodePipeline and AWS CodeBuild
- Manage cross-account deployments with appropriate IAM roles
- Maintain audit trails for infrastructure changes

Some AWS services aren't available in all AWS Regions. For Region availability, see [Service endpoints and quotas](#) in the AWS documentation, and choose the link for the service.

Prerequisites

For this walkthrough, you should have the following:

- An active [Amazon Web Services account](#)
- A Git repository that supports [webhooks](#) and can connect to a webhook URL through the internet- [Github connection](#)
- AWS Command Line Interface [installed](#) and [configured](#) to work with your account
- Python
- Basic knowledge of CloudFormation template and version control
- Code pipeline - set up <https://aws.amazon.com/codepipeline/> and established a connection with a source control provider. Specifically, we are using [GitHub](#) as our source repository to showcase our solution
- Visual Studio Code (VS Code) installed - Download and installation instructions available in [Setting up Visual Studio Code](#).

Targeted business outcomes

The approach in this guide helps organizations achieve the following outcomes:

Feature release management

Use version-specific deployments to roll out new features to isolated environments before promoting to production. This approach reduces release risk and provides early feedback from select customers. For example, you can deploy a commit tagged `preview-20230725-008` to an isolated environment for early customer validation while production remains on a stable release.

Incident response

Deploy hotfixes rapidly by tagging specific commits for expedited promotion to production. This reduces mean time to recovery (MTTR) and minimizes the testing overhead for critical fixes. Teams can create a hotfix branch, tag it (for example, `v1.0.1-hotfix`), and deploy through an expedited approval process.

Sales and demo operations

Create ephemeral environments on demand by deploying specific version tags for client demonstrations. This accelerates the sales cycle without affecting production stability. Sales teams can request exact product versions spun up for prospect engagements.

Compliance and audit readiness

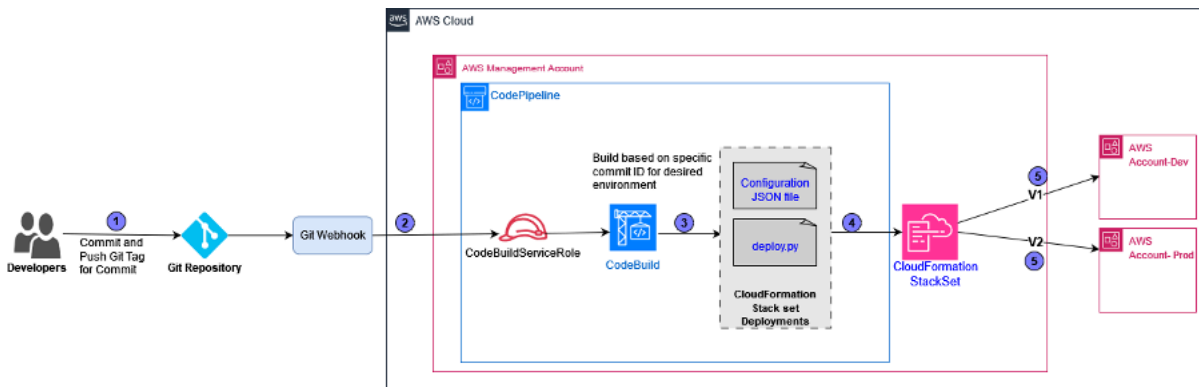

Reference specific commit IDs to verify point-in-time infrastructure configurations during audits. For example, an auditor can request the configuration state at `prod-20240701-010` and the team can reproduce that exact infrastructure state. This simplifies compliance verification and provides a complete audit trail.

A/B testing infrastructure

Deploy parallel variants of infrastructure by using different version tags (for example, `preprod-20230710-011A` and `preprod-20230710-011B`) to compare performance. This supports data-driven decisions for feature implementations.

Solution overview

AWS CodePipeline integrates with source control repositories and automatically triggers pipeline execution when code is committed. In this deployment strategy, the pipeline references an environment configuration file to select the appropriate version for each target environment. By using a centralized version-mapping configuration, the pipeline fetches the corresponding CloudFormation template versions for specific environments, providing consistent and controlled deployments across development, staging, and production.

Code versioning and tagging

Developers commit infrastructure code to the Git repository and create semantic version tags, establishing a clear, traceable deployment baseline. a) Semantic Version Structure - - Format: MAJOR.MINOR.PATCH (e.g., 1.2.3) - MAJOR: Breaking changes - MINOR: New features, backward compatible - PATCH: Bug fixes, backward compatible b) Git commands for version tagging:

```
# Create and push a new version tag
git tag -a v1.0.0 -m "Initial production release"
git push origin v1.0.0
```

c) Version mapping configuration: Use a `deployment_map.json` file to manage versions across environments. This file contains environment-specific version mappings, account IDs, and Regions. The infrastructure team should configure and maintain this file. Sample `deployment_map.json` file:

```
{
  "environments": {
    "dev": {
```

```
        "version_constraint": "= <Version_ID-1>",
        "account_id": "<Account_ID-1>",
        "region": "<region_name>"
    }
    "prod": {
        "version_constraint": "= <Version_ID-2>",
        "account_id": "<Account_ID-2>",
        "region": "<region_name>"
    }
}
}
```

This configuration enables you to:

- Map specific versions to each environment
- Maintain separate account configurations
- Control regional deployments
- Progressively promote changes through environments

Automated webhook trigger

To connect your GitHub repository to CodePipeline:

1. Open the CodePipeline console and navigate to your pipeline settings.
2. Generate a webhook URL and copy it.
3. In your GitHub repository, navigate to **Settings**, then **Webhooks**, then choose **Add webhook**.
4. Paste the CodePipeline webhook URL in the **Payload URL** field.
5. Set **Content type** to application/json.
6. Select **Just the push event** for the trigger.
7. Choose **Add webhook** to save.
8. Verify the connection by pushing a change to your repository and confirming that CodePipeline triggers automatically.

When implemented, each code push automatically triggers your deployment pipeline, maintaining version control and providing consistent infrastructure updates across environments.

Version-based deployment

The Git webhook triggers an AWS CodeBuild project. CodeBuild runs the deployment process by using two key components: the version mapping configuration (`deployment_map.json`) and a deployment script (`deploy.py`). Ensure your CodeBuild project has:

- An IAM role with permissions for CloudFormation operations
- Cross-account deployment permissions if deploying to multiple accounts
- Python 3.x and boto3 installed in the build environment

The deployment script performs these sequential actions:

1. Reads `deployment_map.json` to get environment configurations.
2. Extracts the current version from the `CODEBUILD_RESOLVED_SOURCE_VERSION` environment variable.
3. Matches the version with environment constraints in `deployment_map.json`.
4. Identifies the target account and Region for deployment.
5. Creates or updates the CloudFormation stack in the target environment. Sample `deploy.py` file:

```
import json
import boto3
import os

def deploy_stack():
    # Load deployment configuration
    with open('deployment_map.json', 'r') as f:
        config = json.load(f)

    # Get current version from CodeBuild environment
    version = os.environ['CODEBUILD_RESOLVED_SOURCE_VERSION']

    for env, settings in config['environments'].items():
        if settings['version_constraint'].split()[1] == version:
            cloudformation = boto3.client('cloudformation',
                                          region_name=settings['region'])
```

```
# Deploy CloudFormation stack
cloudformation.create_or_update_stack(
    StackName=f'infrastructure-{env}',
    TemplateURL='path/to/your/template.yaml', # Ensure CloudFormation
templates are in your repository
    Parameters=[
        {
            'ParameterKey': 'Environment',
            'ParameterValue': env
        }
    ]
)

if name == '__main__':
    deploy_stack()
```

Note

This sample uses `create_stack`. For production use, implement logic to check whether the stack exists and call `update_stack` if it does, or use CloudFormation change sets for safer updates.

CloudFormation stack creation

The deployment script automatically handles stack creation through CodeBuild:

- Each environment defined in `deployment_map.json` gets its own stack.
- Stack names are automatically generated by using the format: `infrastructure-{environment}`.
- Version control is maintained through the `version_constraint` in `deployment_map.json`.
- Stacks are created or updated based on the version tags.

Example stack names:

- For the dev environment: `infrastructure-dev`
- For the prod environment: `infrastructure-prod`

Multi-account deployment

To deploy across multiple AWS accounts, configure IAM roles in each account: **In the administrator account (where CodeBuild runs):**

1. Create a role named `AWSCloudFormationStackSetAdministrationRole`.
2. Grant permissions for CloudFormation and StackSet management.

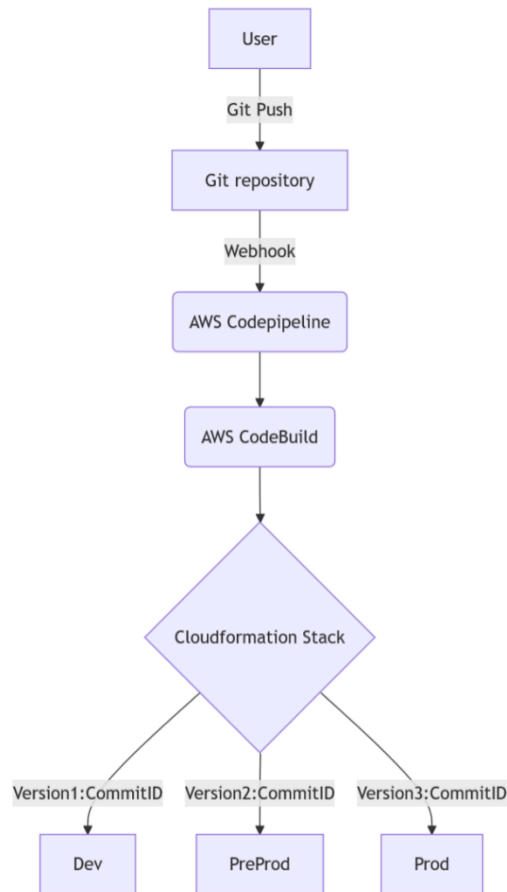

In each target account:

1. Create a role named `AWSCloudFormationStackSetExecutionRole`.
2. Configure a trust relationship with the administrator account.
3. Grant permissions for CloudFormation resource creation.

Example IAM policy for cross-account role assumption:

```
``json
{
  "Version": "2012-10-17",
  "Statement": [
    {
      "Effect": "Allow",
      "Action": "sts:AssumeRole",
      "Resource": [
        "arn:aws:iam::<account-id>:role/CodeBuildCrossAccountRole"
      ]
    }
  ]
}
```

The `deployment_map.json` file handles target specification. The `deploy.py` script automatically reads target accounts and Regions from `deployment_map.json` and maps versions to specific environments. For detailed IAM role setup instructions, see [Grant self-managed permissions](#) in the CloudFormation documentation. This is the CI/CD workflow for version-controlled CloudFormation deployments across environments:

Hotfix deployments

For urgent production fixes:

1. Create a hotfix branch from the production version.
2. Implement and test the change.
3. Create a specific version tag (for example, v1.0.1-hotfix).
4. Deploy by using an expedited approval process.
5. Monitor the deployment and verify the fix.
6. Document changes for audit purposes.

Best practices

These are best practices for version control and tagging strategies.

- Use semantic versioning (MAJOR.MINOR.PATCH) consistently across all environments to maintain clear version tracking.
- Use consistent version tagging conventions (for example, v1.0.0, v1.2.0) to maintain a clear deployment history.
- Maintain the `deployment_map.json` file in the same repository as your CloudFormation templates to keep version mappings under source control.
- Document all version changes and their impacts in commit messages and release notes.
- Implement branching strategies that separate feature development from hotfix workflows.
- Create hotfix branches from the current production version tag and use a dedicated naming convention (for example, v1.0.1-hotfix) to distinguish hotfixes from regular releases.
- Configure error handling, logging, and retry mechanisms in your CI/CD pipeline by using the `buildspec.yml` file.
- Use environment variables for sensitive information rather than hardcoding values in configuration files.
- Follow the principle of least privilege and grant the minimum permissions required to perform a task. For more information, see [Security best practices](#) in the IAM documentation.
- Configure IAM roles for cross-account access by using role assumption with least-privilege policies.
- Monitor and audit cross-account access patterns by using AWS CloudTrail.
- Rotate access credentials regularly and maintain separate security groups for different environments.
- Maintain detailed deployment logs and historical configuration records for audit purposes.
- Enable CloudTrail for API activity logging across all deployment accounts.
- Implement approval workflows for production deployments to maintain change control.
- Validate CloudFormation templates by using `cfn-lint` before committing to catch syntax errors early.
- Conduct impact assessments before promoting version tags to production environments.
- Establish communication plans for deployments that might cause service interruptions.

- **Maintain rollback procedures and contingency plans for each deployment.**

Troubleshooting

If a deployment fails, follow this resolution process:

1. Check Amazon CloudWatch Logs for specific error messages related to the failed stack operation.
2. Verify IAM permissions and role assignments for the deployment account.
3. Review the `deployment_map.json` configuration for correct version constraints, account IDs, and Region values.
4. Validate the CloudFormation template syntax by using the CloudFormation Linter (`cfn-lint`).
5. If the issue persists, roll back to the last known good version by updating the version constraint in `deployment_map.json` to the previous commit ID.

Next steps

This guide described how commit ID-based tagging provides version control for CloudFormation deployments by using CodePipeline and CodeBuild. To build upon this foundation focus on these key areas:

1. **Evaluate environment needs** — Review your environment configurations and assess version mapping requirements across development, staging, and production environments. Consider cross-account deployment needs and plan for scaling infrastructure deployments as your organization grows.
2. **Implement monitoring and logging** — Establish comprehensive monitoring for your deployment pipelines by using CloudWatch. Configure appropriate alerts and notifications to maintain visibility into your infrastructure changes.
3. **Review security and compliance** — Regularly audit your IAM roles, cross-account access configurations, and security group settings. Ensure your implementation adheres to organizational compliance standards and security best practices.
4. **Enable team adoption** — Create clear documentation and conduct team training to ensure successful adoption of these practices. Establish standardized deployment workflows and approval processes.

Numbers

7 Rs

Seven common migration strategies for moving applications to the cloud. These strategies build upon the 5 Rs that Gartner identified in 2011 and consist of the following:

- **Refactor/re-architect** – Move an application and modify its architecture by taking full advantage of cloud-native features to improve agility, performance, and scalability. This typically involves porting the operating system and database. Example: Migrate your on-premises Oracle database to the Amazon Aurora PostgreSQL-Compatible Edition.
- **Replatform (lift and reshape)** – Move an application to the cloud, and introduce some level of optimization to take advantage of cloud capabilities. Example: Migrate your on-premises Oracle database to Amazon Relational Database Service (Amazon RDS) for Oracle in the AWS Cloud.
- **Repurchase (drop and shop)** – Switch to a different product, typically by moving from a traditional license to a SaaS model. Example: Migrate your customer relationship management (CRM) system to Salesforce.com.
- **Rehost (lift and shift)** – Move an application to the cloud without making any changes to take advantage of cloud capabilities. Example: Migrate your on-premises Oracle database to Oracle on an EC2 instance in the AWS Cloud.
- **Relocate (hypervisor-level lift and shift)** – Move infrastructure to the cloud without purchasing new hardware, rewriting applications, or modifying your existing operations. You migrate servers from an on-premises platform to a cloud service for the same platform. Example: Migrate a Microsoft Hyper-V application to AWS.
- **Retain (revisit)** – Keep applications in your source environment. These might include applications that require major refactoring, and you want to postpone that work until a later time, and legacy applications that you want to retain, because there's no business justification for migrating them.

- **Retire** – Decommission or remove applications that are no longer needed in your source environment.

- Migration – Migrating individual applications
- Re-invention – Optimizing products and services, and innovating in the cloud

These stages were defined by Stephen Orban in the blog post [The Journey Toward Cloud-First & the Stages of Adoption](#) on the AWS Cloud Enterprise Strategy blog. For information about how they relate to the AWS migration strategy, see the [migration readiness guide](#).

CMDB

See [configuration management database](#).

code repository

A location where source code and other assets, such as documentation, samples, and scripts, are stored and updated through version control processes. Common cloud repositories include GitHub or Bitbucket Cloud. Each version of the code is called a *branch*. In a microservice structure, each repository is devoted to a single piece of functionality. A single CI/CD pipeline can use multiple repositories.

cold cache

A buffer cache that is empty, not well populated, or contains stale or irrelevant data. This affects performance because the database instance must read from the main memory or disk, which is slower than reading from the buffer cache.

cold data

Data that is rarely accessed and is typically historical. When querying this kind of data, slow queries are typically acceptable. Moving this data to lower-performing and less expensive storage tiers or classes can reduce costs.

conformance pack

A collection of AWS Config rules and remediation actions that you can assemble to customize your compliance and security checks. You can deploy a conformance pack as a single entity in

an AWS account and Region, or across an organization, by using a YAML template. For more information, see [Conformance packs](#) in the AWS Config documentation.

continuous integration and continuous delivery (CI/CD)

The process of automating the source, build, test, staging, and production stages of the software release process. CI/CD is commonly described as a pipeline. CI/CD can help you automate processes, improve productivity, improve code quality, and deliver faster. For more information, see [Benefits of continuous delivery](#). CD can also stand for *continuous deployment*. For more information, see [Continuous Delivery vs. Continuous Deployment](#).

CV

See [computer vision](#).

D

data at rest

Data that is stationary in your network, such as data that is in storage.

data classification

A process for identifying and categorizing the data in your network based on its criticality and sensitivity. Data classification is a component of the security pillar in the AWS Well-Architected Framework. For more information, see [Data classification](#).

strangler fig pattern

An approach to modernizing monolithic systems by incrementally rewriting and replacing system functionality until the legacy system can be decommissioned. This pattern uses the analogy of a fig vine that grows into an established tree and eventually overcomes and replaces its host. test environment

See [environment](#).

training

To provide data for your ML model to learn from. The training data must contain the correct answer. The learning algorithm finds patterns in the training data that map the input data attributes to the target (the answer that you want to predict). It outputs an ML model that captures these patterns. You can then use the ML model to make predictions on new data for which you don't know the target.

trusted access

Granting permissions to a service that you specify to perform tasks in your organization in AWS Organizations and in its accounts on your behalf. The trusted service creates a service-linked role in each account, when that role is needed, to perform management tasks for you. For more information, see [Using AWS Organizations with other AWS services](#) in the AWS Organizations documentation.

A concept that refers to imprecise, incomplete, or unknown information that can undermine the reliability of predictive ML models. There are two types of uncertainty: *Epistemic uncertainty* is caused by limited, incomplete data, whereas *aleatoric uncertainty* is caused by the noise and randomness inherent in the data.

zero-shot prompting

Providing an [LLM](#) with instructions for performing a task but no examples (*shots*) that can help guide it. The LLM must use its pre-trained knowledge to handle the task. The effectiveness of zero-shot prompting depends on the complexity of the task and the quality of the prompt. See also [few-shot prompting](#).
